Edited by Lukas Huber

Abstract Direct cell-cell communication mediated by plasma membrane-spanning gap junction (GJ) channels is vital to all aspects of cellular life. Obviously, GJ intercellular communication (GJIC) requires precise regulation, and it is known that controlled biosynthesis and degradation, and channel opening and closing (gating) are exploited. We discovered that cells internalize GJs in response to various stimuli. Here, we report that GJ internalization is a clathrin-mediated endocytic process that utilizes the vesicle-coat protein clathrin, the adaptor proteins adaptor protein complex 2 and disabled 2, and the GTPase dynamin. To our knowledge, we are first to report that the endocytic clathrin machinery can internalize double-membrane vesicles into cells. © 2008 Federation of European Biochemical Societies. #### 1. Introduction

The role of clathin in vesicle endocytosis is well documented. Clathrin forms a typical curved lattice around endocytic vesicles that are internalized at the plasma membrane (PM) [1]. However, clathrin has also been implicated in the internalization of viruses, pathogenic bacteria, and even latex beads [2–4]. We have discovered an additional clathrin-mediated endocytosis (CME) process that results in the internalization of double-membrane vesicles from the PMs of cells that are coupled by gap junctions (GJs) [5].

GJs consist of transmembrane channels that bridge the PMs to provide direct intercellular communication. GJ channels cluster into so-called "plaques" containing a few to tens of thousands of channels. The channels facilitate diffusion of ions and small molecules, thus coupling the connected cells electrically and metabolically. GJ function has been determined vital for embryonic development, regulating differentiation and growth, and in maintaining tissue homeostasis. The essential role of GJ intercellular communication (GJIC) is manifested

Abbreviations: AGJ, annular gap junction; AP-2, adaptor protein complex 2; CHC, clathrin heavy chain; CME, clathrin-mediated endocytosis; Cx, connexin; Dab2, disabled 2; GJ, gap junction; KD, knockdown; PM, plasma membrane; RNAi, RNA interference; Trfn, transformin

by numerous known mutations in GJ proteins, which have been linked to deafness, neuropathies, cataracts, skin disorders, and defects in cranio-facial development.

Two half-channels, or connexons, each synthesized by one of the coupled cells, dock head-to-head in the extracellular space to form the complete GJ channel. Six transmembrane proteins, termed connexins (Cxs), oligomerize around a central hydrophilic pore to shape the connexon. Connexin proteins represent a large gene-family with connexin 43 (Cx43) being most ubiquitously expressed. It is evident, that GJIC needs to be regulated precisely for proper cellular function. GJ channel activity is regulated by both, channel opening and closing (gating) in response to physiological parameters, such as intracellular pH, Ca<sup>2+</sup> concentration, and Cx phosphorylation [6–8], and by controlled channel biosynthesis and internalization [9,10]. Regulated GJ channel internalization, for example, is vital to cell migration and wound healing, as well as for cell division, when cells uncouple at beginning of mitosis, and recouple at cytokinesis [11]; and misregulation of GJ channel internalization potentially leads to severe pathological conditions, such as cancer metastasis, pulmonary edema, ischemia, and hemorrhagic fevers.

We discovered that cells internalize their GJs in response to various endogenous and exogenous stimuli, including exposure to inflammatory mediators and non-genomic carcinogens [5] (Gilleron et al., manuscript submitted; Baker et al., manuscript in preparation). GJ internalization results in the formation of cytoplasmic double-membrane GJ vesicles [earlier termed annular gap junctions (AGJs)] that are degraded by lysosomal pathways. Interestingly, the GJ vesicle lumen and the inner vesicle membrane are derived from cytoplasm and PM of the neighboring cell, while the outer vesicle membrane is derived from the PM of the internalizing cell [5,12]. We further found that clathrin, and clathrin-associated proteins colocalize with internalizing GJs and GJ vesicles, suggesting a role for these proteins in GJ internalization [5]. Knocking down protein expression levels using RNA interference (RNAi), we now show that cellular depletion or functional inhibition of clathrin, the clathrin-adaptor protein complex 2 (AP-2) and disabled 2 (Dab2), and of the GTPase dynamin significantly inhibits GJ internalization.

#### 2. Materials and methods

## 2.1. Cell culture and connexin constructs

HeLa cells (CCL 2, American Type Culture Collection, Manassas, VA) were cultured under standard conditions as described [13]. For all experiments cells were grown on round 22 mm diameter glass cover slips coated with poly-L-lysine (Sigma–Aldrich, St. Louis, MO).

Cx43-GFP is described [13]. Cx43-mApple was constructed by replacing GFP by mApple cDNA [14].

#### 2.2. RNAi knockdown (KD) procedures

All RNAi oligonucleotides (oligos) were purchased from Dharmacon RNA Technologies (Lafayette, CO). Clathrin heavy chain (CHC) oligos were SMARTpool option CLTC (M-004001-00). AP-2 α-adaptin subunit RNAi oligos were SMARTpool option AP2 A1 (M-012492-00). Dab2 RNAi oligos were sequence 5'–UUCUU-UAGAGAAAAUCCAUU-3' published in [15]. Dynamin2 RNAi oligos were SMART pool option DNM2 (L-004007-00).

Previously described KD procedures were followed [5]. Briefly, oligonucleotides were transfected into HeLa cells using Oligofectamine (Invitrogen, Carlsbad, CA), followed 48 h later by Cx43-GFP cDNA [13] using Superfect (Qiagen, Valencia, CA) as recommended by the manufacturers. Oligo transfection efficiency was tested using a fluorescent-labeled control (siGLO RISC-Free fluorescently-labeled, non-targeting oligonucleotide, Dharmacon) and was more than 90% efficient. Cells were assayed 72 h after oligo transfection. Endocytosis inhibition was monitored by incubation in medium containing 10 µg/ml Alexa-Fluor 488-labeled transferrin (Trfn) (5 mg stock solution in 1× PBS; Molecular Probes) for 3 min, fixation, and microscopic examination.

#### 2.3. Immunoblot analyses

Verification of protein KD was assessed by Western blotting 72 h post-RNAi transfection. Cells were scraped into PBS/protease inhibitor cocktail (Sigma–Aldrich). Cells were lysed in standard 5× sample buffer and boiled for 5 min. Samples were resolved on 10% Bis/Acrylamide (1:29) gels and transferred onto nitrocellulose membrane (pore size 0.2 µm, Millipore Corporation, Bedford, MA). Following blocking, membranes were incubated in primary antibodies (1:1000 in 4% BSA in PBST) for 1 h at RT or o/n at 4 °C. Membranes were washed in PBST for 15 min and incubated with horseradish peroxidase (HRP) – conjugated anti-mouse and anti-rabbit secondary antibody (1:5000 in 4% BSA in PBST, Zymed Laboratories) for 1 h at RT or o/n at 4 °C. Immunoreactive bands were detected using an Immun-star HRP chemiluminescent kit (BioRad Laboratories, Hercules, CA). The signal was quantified by scanning developed films using SCION software (NIH).

#### 2.4. Antibodies and immunofluorescence analyses

Mouse mAB anti-clathrin heavy chain (HCH) X22, a rabbit polyclonal antiserum directed against the  $\beta$ -subunit of AP-2 (GD/1, anti  $\beta$ 1/ $\beta$ 2), mouse mAB anti- $\alpha$ -Adaptin (AP-2  $\alpha$ -subunit) (MA1-64; Affinity BioReagents, Golden, CO), mouse mAB anti- $\alpha$ -Adaptin (610501; BD Biosciences, San Jose, CA), mouse mAB anti-Dab2 (p96, BD Biosciences), and mouse mAB anti-Dynamin2 (clone 41; BD Biosciences) were used at dilutions of 1:50–1:250 in 10% FBS/PBS. Secondary antibodies and immunofluorescence analyses have been described previously [5]. KD of proteins was evaluated by comparing the fluorescence intensity signals measured along lines on images taken under identical exposure conditions from treated and untreated cells.

#### 2.5. Dynamin assays

Cells were transfected with Cx43-GFP, and 14 h later dynamin function was inhibited by treating cells with 10  $\mu M$  GTP $\gamma S$  (Sigma, 10 mM stock in water, for 5 h), or with 40  $\mu M$  dynasore 14 h post-transfection and again with 20  $\mu M$  dynasore 17 h post-transfection (Tocris Bioscience, Ellisville, MO, 20 mM stock in DMSO, for a total of 5 h). Additionally, cells were cotransfected with Cx43-mApple, and GFP-tagged dominant negative Dynamin2-K44A mutant. Number and size of GJs and GJ vesicles (AGJs) was evaluated 19 h after transfections as described for the KD assays.

#### 2.6. Statistical analyses

AGJs and GJs were counted on images taken of KD, drug treated and control cells in at least three independent experiments each. Only clearly defined GJs (a line of fluorescent puncta, or elongated plaques located between cell pairs), and AGJs (bright fluorescent spherical structures located in the cytoplasm ≥ 0.5 µm in diameter, see Ref. [5]) were considered. Statistical analyses were performed using Microsoft Excel's analysis of variance (ANOVA) "Single Factor and Descriptive Statistics" functions of the data analysis package. For sta-

tistical analyses, the total number of AGJ vesicles was divided by the number of cell pairs that were positive for Cx43-GFP/-mApple expression and clearly coupled by GJs. Similarly, the total number and length of GJ plaques was determined and divided by the number of cell pairs. In all analyses, a P-value  $\leq 0.05$  was considered statistically significant.

#### 3. Results

## 3.1. Depletion of clathrin significantly reduces GJ internalization

Using live-cell imaging, our lab and others have shown previously that cells internalize entire GJ plaques and plaque portions in a highly regulated process, with one cell of a pair preferentially budding GJs outward, and the other cell preferentially internalizing the double-membrane spanning GJ plaques [5,12]. We further found that internalizing GJs specifically colocalized with clathrin, the alternative clathrin adaptor Dab2, dynamin2, myosin-VI, and actin filaments, using both, monoclonal and polyclonal antibodies. Additionally, we found that cultivating Cx43-GFP transfected HeLa cells in hypertonic medium, a treatment described to prevent clathrin and adapter proteins from interacting [16], or depleting cells of clathrin using CHC RNAi significantly reduced GJ internalization by 56% and 55%, respectively [5]. Together, these investigations suggested a critical role for clathrin in the internalization of Cx43-based GJs. However, since clathrin is a major component of cellular metabolism, depletion of this protein could have reduced unspecifically Cx biosynthesis and trafficking, and thus GJ formation. If clathrin mediates the internalization of GJs, then clathrin depletion should correlate with a reduction of AGJ vesicles and a concomitant increase in GJ plaque size and/or number. To test this, we repeated RNAimediated CHC KD experiments in HeLa cells. Significant CHC depletion (>90%) at 72 h post-RNA-oligo transfection was confirmed by Western blot analyses (Fig. 1A). In addition, immunofluorescence and fluorescence intensity analyses revealed significantly reduced CHC staining (Fig. 1B and C), and functional studies showed an almost complete inhibition of Trfn uptake (Fig. 1D and E), indicating efficient CHC depletion and CME inhibition.

CHC-depleted or control treated HeLa cells were transiently transfected with Cx43-GFP cDNA 48 h post-RNAi transfection. In HeLa cells (that do not express endogenous Cxs), GJ plaques form only between transfected groups of cells (Fig. 2A, arrows). Cells were allowed to make and internalize GJ plaques for an additional 24 h before fixation. Fields with clearly defined GJ plaques between cells were imaged (Fig. 2A, arrows), and AGJ and GJ plaque number and size were quantified (see Section 2, Fig. 2B and C). As in our previous study [5], we observed a significant reduction in the number of GJ vesicles that were internalized under CHC KD conditions (50% compared to control cells; Fig. 2B and C). In addition, we found a significant increase in the size and number of PM GJs (97% and 30%) increase compared to control cells, Fig. 2B and C). Together, a decrease in internalized GJ vesicles, and a concomitant increase in GJ plaque size and number strongly suggests that GJ internalization is a clathrin-mediated process.

# 3.2. Depletion of clathrin adaptors significantly reduces GJ internalization

CME requires adaptor proteins that bind to both cargo and cargo receptors, and to clathrin to form endocytic vesicles. The

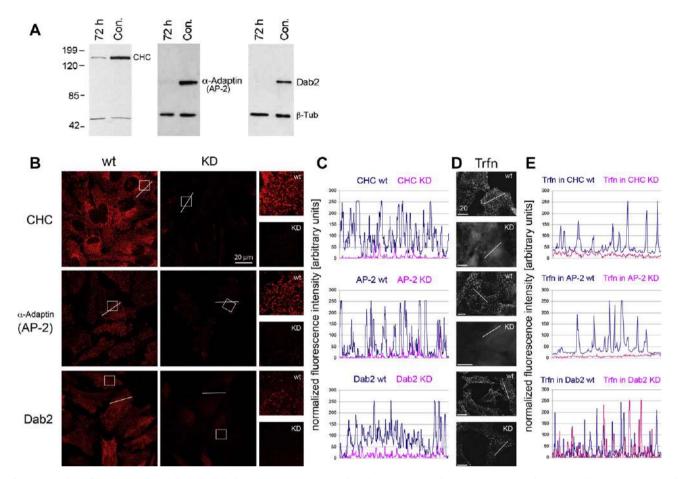

Fig. 1. RNAi-mediated KD of clathrin heavy chain (CHC), and the clathrin adaptors α-Adaptin (AP-2) and Dab2 in HeLa cells. (A) Over 90% of respective protein levels were depleted when assayed 72 h post-oligo transfection by Western blot analyses. Equal gel loading was verified by β-tubulin (β-Tub) staining. (B) Efficient protein depletion verified by immunofluorescence staining (images were captured at identical parameters). Boxed areas are shown enlarged on the right. (C) Line-plots of fluorescence intensity measured along respective lines (shown in the images in B). (D) Inhibition of CME monitored by fluorescence labeled transferrin (Trfn) uptake. (E) Line-plots of fluorescence Trfn intensity measured along respective lines (shown in the images in D).

adaptor protein complex AP-2 is commonly used for cargo internalization at the PM. Surprisingly, we detected only a very limited colocalization of AP-2 with internalizing GJs, or GJ vesicles [5]. On the other hand, we discovered a robust colocalization of the alternative clathrin adaptor protein Dab-2 with GJs and GJ vesicles, even in cells in which only low amounts of Dab2 are expressed [5]. Because of the prominent role of AP-2 in CME, and the pronounced colocalization of Dab2 with GJs/GJ vesicles, we examined whether either of these adaptors plays a critical role in GJ internalization. Thus, we performed RNAi-mediated KDs of these adaptor proteins in Cx43-GFP transfected HeLa cells. Efficient AP-2 and Dab-2 depletion was confirmed by Western blot analyses (>90%; Fig. 1A). A clear reduction of vesicular fluorescence signals (Fig. 1B and C), and significant inhibition of Trfn uptake was detected in AP-2 depleted cells (Trfn uptake is known not to be affected in Dab2 depleted cells) [17] (Fig. 1D and E). Counting GJs and GJ vesicles in KD and control cells revealed that significantly fewer (38% and 28%) GJ vesicles were generated in the AP-2 and Dab2 KD cells, respectively (Fig. 2), while at the same time, GJ size and/or number increased significantly by 81% and 37% in AP-2, and 48% in Dab2 depleted cells (a slight, insignificant reduction in GJ number by 4% was observed in Dab2 depleted cells). Taken together, as observed for clathrin KD cells, depletion of either AP-2 or Dab-2 resulted in a statistically significant inhibition of GJ internalization, coinciding with an increase in GJ plaque size and/or number. These results strongly support a role for both adaptors in GJ internalization.

# 3.3. Depletion of dynamin significantly reduces GJ internalization

Another protein that is recruited to clathrin-coated pits is the GTPase dynamin, which functions in the completion of vesicle budding [18]. Since we also observed a robust colocalization of this protein with internalizing GJs and GJ vesicles [5], we depleted dynamin in Cx43-GFP expressing HeLa cells. Efficient dynamin2 (Dyn2) (the isoform expressed in HeLa cells) depletion was confirmed by Western blot analyses (>90%; Fig. 3A), and by a significant reduction of the vesicular dynamin2 fluorescence signal (Fig. 3B and C). Counting GJs and GJ vesicles in KD and control cells revealed that significantly fewer (29%) GJ vesicles were generated in the dynamin2 KD cells, while at the same time, GJ size increased significantly by 39% (Fig. 3F–H). Again, a slight insignificant reduction in GJ number by 9% was observed in these experiments.

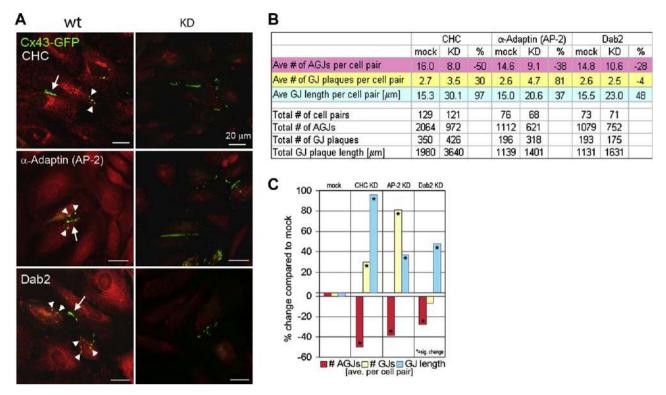

Fig. 2. GJ internalization is significantly reduced in CHC, α-Adaptin and Dab2 RNAi-treated cells. (A) Representative images of mock (wt), and RNAi-(KD) treated cells with Cx43-GFP GJs (arrows), and internalized GJ vesicles (arrowheads) marked. (B, C) Quantitative analyses of total and average GJ length (blue) and numbers (yellow), and numbers of internalized GJs (red) per cell pair in KD and control cells.

Since the dynamin KD resulted in a less significant inhibition of GJ internalization than the clathrin KD (28% versus 50–55%), we decided to further investigate the role of dynamin in GJ internalization. We therefore overexpressed GFP-tagged dominant negative dynamin2-K44A mutant in Cx43-mApple expressing cells, or treated Cx43-GFP expressing HeLa cells either with the dynamin inhibitor, dynasore, or the GTPase inhibitor, GTP $\gamma$ S. All these treatments significantly inhibited Trfn uptake (Fig. 3D and E).

Counting GJs and GJ vesicles in drug-treated and control cells revealed that significantly fewer GJ vesicles were generated under these conditions (53%, 50%, and 33%, respectively Fig. 3G and H), while at the same time, GJ number and size increased significantly by 69% and 13% in Dyn2-K44A over-expressing cells. A reduction in GJ number and size by 11% and 25% was observed in dynasore treated cells and by 3% and 18% in GTP $\gamma$ S-treated cells, probably due to the general inhibition of GTPases by these drugs. Together, these results suggest that dynamin2 is also involved in GJ internalization.

Since all described protein depletions resulted in a reduced GJ internalization, and an increased GJ plaque size and/or number, we transfected cells with unrelated RNAi oligonucle-otides (lamin A/C), expressed in HeLa cells; dynamin1, not expressed in HeLa cells; and a non-targeting oligo (siGLO RISC-Free). None of these control RNAi transfections had a significant impact on GJ internalization (data not shown).

## 4. Discussion

Using RNAi technology we down-regulated the expression of endocytic proteins and investigated the impact on GJ inter-

nalization. Proteins examined were found previously to colocalize with internalizing GJs [5]. We found a significant reduction of internalized GJs, and a concomitant significant increase in GJ size and/or number in all relevant KD experiments, indicating that GJ internalization is a clathrin-mediated process that also utilizes the clathrin adaptors AP-2 and Dab2, and the GTPase dynamin. A complete inhibition of GJ internalization was not observed in these KD experiments, possibly because (I) residual protein levels remained in the KD cells (<10%), (II) Cx43-GFP transfection and initial expression occurred at a time when KD protein levels were still significantly higher (48 versus 72 h), and/or (III) cells may internalize GJs by an alternate clathrin-independent pathway, especially under conditions when CME is inhibited.

Although KD of AP-2 resulted in a significant reduction in GJ internalization (38%), we were unable to detect a convincing colocalization of this protein complex with internalizing GJs, (despite using antibodies directed either against the  $\alpha$ - or the β-subunit) [5]. This might indicate that the relevant AP-2 epitopes are masked during its interaction with Cxs, or that AP-2 is only transiently, or to a limited extent involved in clathrin recruitment. The latter hypothesis is supported by our observation that AP-2 KD resulted in a less significant reduction in GJ internalization as compared to clathrin KDs (38% versus 50-55%), and by the fact that a second clathrin adaptor, Dab2, is recruited efficiently to internalizing GJs [5], and its depletion also resulted in significant reduction of GJ internalization (by 28%). Another possibility is that these clathrin adaptors act in concert, and/or that another, redundant clathrin adaptor is recruited in our KD experiments. Indeed, recent evidence suggests that numerous clathrin adaptors are localized within a single clathrin-coated vesicle [15], and that these adaptors have

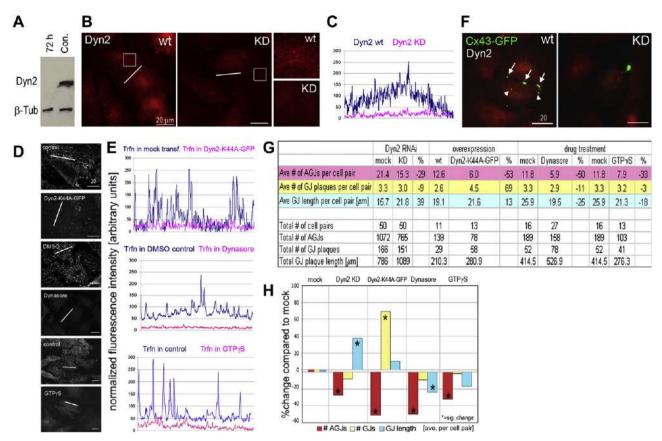

Fig. 3. RNAi-mediated depletion and functional inhibition of dynamin significantly reduces GJ internalization. Boxed areas are shown enlarged on the right. (C) Line-plots of fluorescence intensity measured along respective lines (shown in the images in B). (D) Inhibition of CME in HeLa cells overexpressing dominant negative Dyn2-K44A-GFP mutant, or were treated with Dynasore, or GTPγS monitored by fluorescence labeled Trfn uptake. (E) Line-plots of fluorescence Trfn intensity measured along respective lines (shown in the images in D). (F) Representative images of mock (wt), and Dyn2 RNAi- (KD) treated cells with Cx43-GFP GJs (arrows), and internalized GJ vesicles (arrowheads) marked. (G, H) Quantitative analyses of total and average GJ length and numbers, and numbers of internalized GJs per cell pair in treated and control cells.

multiple, partially overlapping functions. Dab2, for example, can interact directly with cargo through a tyrosine-based internalization motif, with CHC, with the membrane lipid phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>), and, through its C-terminal serine- and proline rich region, with myosin-VI to facilitate vesicle translocation [5,19]. Recently, a critical role for PIP<sub>2</sub> in CME has been shown [20]; and in Dab2<sup>-/-</sup> mice, LDL-receptor uptake (a typical Dab2 cargo), was found to be accomplished by the redundant clathrin adaptor ARH [21]. Interestingly, overlapping putative AP-2 and Dab2 internalization motifs are present in the C-terminus of Cx43 and of other connexins [5], and mutations within this region significantly increased the half-life of Cx43 [22].

We also found a pronounced colocalization of dynamin with GJs and internalized GJ vesicles [5]. Dynamin has been shown to be involved in the majority of endocytic processes [4,18,23,24]. It is known to be recruited to clathrin-coated pits, and to contribute to the fission of clathrin-coated vesicles [18,25]. We found a significant, 29% less efficient internalization of GJs in dynamin KD cells, and experiments in which we inhibited dynamin function (GTPγS and dynasore treatment, or overexpression of GFP-tagged dominant negative Dyn2-K44A) reduced internalization by 33–53%, further supporting the role of dynamin in GJ internalization. Future research will address how, mechanistically, these proteins

internalize double-membrane regions that can be 50 times larger than a typical endocytic vesicle [18].
