Relative Raman Cross-Sections of Tungsten Oxides: 
[WO₃, Al₂(WO₄)₃ and WO₃/Al₂O₃]

Laser Raman spectroscopic studies of alumina-supported WO₃ catalysts have shown that three different tungsten oxide phases are present in WO₃/Al₂O₃ catalysts: WO₃, Al₂(WO₄)₃, and a surface tungsten oxide species (1–8). The concentrations of these phases in WO₃/Al₂O₃ catalysts depend on tungsten oxide loading and temperature of calcination. Previous studies have shown that Raman spectroscopy is more sensitive to WO₃ and Al₂(WO₄)₃ than the surface tungsten oxide complex. No attempt, however, has been made to estimate the relative Raman cross sections of these tungsten oxide phases. This information is essential for a model to be developed of the WO₃/Al₂O₃ system. In this note the relative Raman intensities of WO₃, Al₂(WO₄)₃, and the surface tungsten oxide species on alumina are determined, and this information is used to examine previous conclusions about the WO₃/Al₂O₃ system.

Samples of pure WO₃ and pure Al₂(WO₄)₃ were obtained from Cerac and their structures were confirmed by X-ray diffraction. A 10 wt% WO₃ supported on γ-Al₂O₃ (Harshaw, Al-4104E, 220 m²/g) was prepared by the incipient wetness or dry impregnation method using ammonium metatungstate (Sylvania, Inc.) and subsequently calcining at 500, 1000, and 1050°C for 16 h. In addition, 15 and 25 wt% WO₃ on γ-Al₂O₃ (Engelhard Industries, reforming grade) samples were prepared on the 180 m²/g alumina support. The surface area of the 15 and 25% supported oxides were reduced to 120 m²/g by steaming these WO₃ on Al₂O₃ samples at 760°C as described elsewhere (7). An argon ion laser (Spectra Physics, Model 165) was tuned to the 514.5-nm line for excitation. A prism monochromator (Anaspec Model 300S) which has a typical band width of 0.3 nm was used to remove the laser plasma lines. A cylindrical lens (f = 250 mm) and a variable spherical lens (f = 90–100 mm) were used to achieve an elliptically focused image on the sample. Each sample of about 0.2 g was pelletized under 10 kpsi pressure into a 13-mm-diameter wafer for mounting on a sample holder capable of spinning. The laser power at the sample location was changed by inserting neutral density filters. The scattered light was collected by a lens (f/1.2, f/55 mm) held at about 45° with respect to the excitation. The Raman spectrometer was a triple monochromator (Instruments SA, Model DL203) equipped with holographic gratings and F4 optics. The spectrometer was coupled to an optical multichannel analyzer (Princeton Applied Research, Model OMA2) equipped with an intensified photodiode array detector cooled to −15°C. The total accumulation time needed for each spectrum reported here typically was about 100 sec or less. The digital display of the spectrum was calibrated to give 1.7 cm⁻¹/channel whereas the overall spectral resolution was about 6 cm⁻¹.

The Raman spectra of WO₃, Al₂(WO₄)₃, and 10% WO₃/Al₂O₃ are presented in Fig. 1. The WO₃ structure (distorted ReO₃ structure) is made up of distorted corner-shared WO₃ octahedra. The major vibrational modes of WO₃ are located at 808, 714, and 276 cm⁻¹, and have been assigned to the W=O stretching mode, the W=O bending mode, and the W—O—W deformation mode, respectively (9). Other minor bands are at 708, 327, 243, 218, 185, and 136 cm⁻¹. The Al₂(WO₄)₃ is a defect scheelite structure (distorted CaWO₄ structure) composed
of distorted, isolated tetrahedral tungstate. The major Raman peaks of \( \text{Al}_2(\text{WO}_4)_3 \) are assignable by comparison with tetrahedrally coordinated tungsten oxide in \( \text{WO}_3^- \) (aq.) and \( \text{Na}_2\text{WO}_4 \) (10). \( \text{WO}_3^- \) (aq.) and \( \text{Na}_2\text{WO}_4 \) exhibit major vibrational modes at 933 and 928 cm\(^{-1} \) (symmetric \( \text{W}==\text{O} \) stretch), 830 and 813 cm\(^{-1} \) (antisymmetric \( \text{W}==\text{O} \) stretch), 324 and 312 cm\(^{-1} \) (\( \text{W}==\text{O} \) bending vibrations), respectively. Thus, the \( \text{Al}_2(\text{WO}_4)_3 \) peak at 1052 cm\(^{-1} \) is attributed to the \( \text{W}==\text{O} \) stretching mode and the doublet at 378–394 cm\(^{-1} \) is assigned to the \( \text{W}==\text{O} \) bending mode. The nature of the surface tungsten oxide species in \( \text{WO}_3/\text{Al}_2\text{O}_3 \) catalysts is still not resolved. One group postulated the surface species to be bridged-distorted tungstate octahedra (1–3), while two other groups attributed it to a tetrahedral tungsten oxide complex (4–6). The major Raman transition for the 10% \( \text{WO}_3/\text{Al}_2\text{O}_3 \) occurs around 970 cm\(^{-1} \), and has been assigned to the \( \text{W}==\text{O} \) symmetrical stretch (6). The intensities of the major Raman band for \( \text{WO}_3 \) (808 cm\(^{-1} \)), \( \text{Al}_2(\text{WO}_4)_3 \) (1052 cm\(^{-1} \)) and 10% \( \text{WO}_3/\text{Al}_2\text{O}_3 \) (970 cm\(^{-1} \)) were compared after normalization with respect to the laser power applied. The relative Raman intensity ratios for these transitions are 1600 : 40 : 1 per unit power. These Raman intensity ratios were further scaled for the different tungsten oxide contents which yielded the ratios 160 : 5 : 1 per unit \( \text{WO}_3 \) content.

The relative Raman intensity ratio of \( \text{WO}_3 \) crystallites supported on alumina was also determined as an additional cross-check on the relative Raman intensity ratio estimated from bulk \( \text{WO}_3 \). Both 15 and 25% \( \text{WO}_3/\text{Al}_2\text{O}_3 \) samples of 120 m\(^2\)/g were investigated. The Raman spectrum of the 15% \( \text{WO}_3/\text{Al}_2\text{O}_3 \) sample, which corresponds to approximately a complete monolayer of the surface tungsten oxide species for this alumina support (6, 7), is shown in Fig. 2a. This sample exhibits the Raman bands of the surface tungsten oxide species on the alumina support and a trace amount of crystalline \( \text{WO}_3 \). The 25% \( \text{WO}_3/\text{Al}_2\text{O}_3 \) sample, however, exceeds monolayer coverage.
of tungsten oxide on this alumina support and very intense crystalline WO₃ Raman bands dominate the spectrum (see Fig. 2b). The intensities of the Raman band due to the surface tungsten oxide species are very similar for both WO₃/Al₂O₃ samples as shown in Fig. 3 after scaling for the different applied laser powers over the region 850–1150 cm⁻¹. The very similar Raman intensities of this band confirm that both samples possess a complete monolayer of the surface tungsten oxide species. Furthermore, for the 25% WO₃/Al₂O₃ sample the Raman bands of the WO₃ crystallites dwarf the Raman band of the surface tungsten oxide species. It is reasonable to estimate for the 25% WO₃/Al₂O₃ sample that ⅓ of the tungsten oxide is present as the surface tungsten oxide species and that the remaining ⅔ of the tungsten oxide is present as crystalline WO₃ since the Raman intensities of the surface tungsten oxide species are similar for the 15 and 25% WO₃/Al₂O₃ samples. From this information the relative Raman intensity ratio per unit tungsten oxide of the crystalline WO₃ phase and the surface tungsten oxide phase can be estimated from the data in Fig. 2b. The relative intensity ratio of the major Raman bands for WO₃ (808 cm⁻¹) and the surface tungsten oxide species (970 cm⁻¹) is determined to be 100 per unit WO₃ content, and is not significantly different than the ratio of 160 determined from the Raman measurements of bulk WO₃. Furthermore, the relative intensity of the major Raman band at 808 cm⁻¹ for the 25% WO₃/Al₂O₃ sample from Fig. 2b and bulk WO₃ from Fig. 1 is 0.08, and is not significantly different from the expected value of 0.10. The above measurements confirm the extremely strong Raman cross section possessed by the crystalline WO₃ phase and its apparent independence on WO₃ crystallite size.

From the above data it appears that the light-yellow color of samples containing significant amounts of crystalline WO₃ as well as the sample volume density does not effect the intensity of the Raman signal from WO₃/Al₂O₃ samples. That this does not appear to be a problem is shown by the 15 and 25% WO₃/Al₂O₃ samples of 120 m²/g surface area. The 15% sample was white and the 25% sample was pale yellow. Nevertheless, the Raman bands of the surface tungsten oxide species for both samples have the same intensity as shown in Fig. 3. Also, the intensity of the crystalline WO₃ band in the 25% sample scaled to that of bulk WO₃, with a different density from that of the supported sample, is in good agreement with our cross-section estimates of the two crystalline WO₃ phases. Thus, the data from Figs. 2 and 3 confirm that our cross-section estimates from Fig. 1 are semiquantitative and useful for estimation of the crystalline and amorphous phases present in supported tungsten oxide systems to within experimental error.

Calcination of the 10% WO₃/Al₂O₃ sample previously discussed at 1000°C for an additional 16 h yields the Raman spectrum shown in Fig. 4b. The new spectrum is dominated by the Raman bands of crystal-
NOTES 153

FIG. 4. Comparison of Raman spectra for 10% WO$_3$/Al$_2$O$_3$ calcined at (a) 500°C and (b) 1000°C. Note that the amplified plot of (b) from 800 to 1100 cm$^{-1}$ has the same intensity scale as (a) with the laser power normalized.

X-Ray diffraction, however, does not show the presence of the WO$_3$ phase and suggests that either the WO$_3$ crystals are small (<40 Å) or constitute only a small fraction of the total tungsten oxide in the sample. Furthermore, the Raman intensity of the surface tungsten oxide species on the alumina support is about the same for both calcination temperatures. This implies that only a small amount of the surface tungsten oxide species agglomerated during the high-temperature calcination to form the crystalline WO$_3$ phase. The relative Raman intensity ratio for crystalline WO$_3$ and the tungsten oxide surface species can be used to give a first-order quantitative prediction of the crystalline WO$_3$ content. For the purposes of this estimate the small amount of Al$_2$(WO$_4$)$_3$ present in the 1000°C calcined sample will be ignored. Such a calculation suggests that less than $\frac{1}{3}$ of the total tungsten oxide content is present as crystalline WO$_3$ to yield the Raman spectrum in Fig. 4b, and thereby accounts for the XRD and Raman measurements.

An analogous series of Raman measurements were made on the relative Raman cross section of Al$_2$(WO$_4$)$_3$. The 10% WO$_3$/Al$_2$O$_3$ sample originally calcined at 500°C was calcined at 1050°C for an additional 16 h to quantitatively convert the surface tungsten oxide species to Al$_2$(WO$_4$)$_3$ as shown in Fig. 5. The relative intensity of the major Raman bands for Al$_2$(WO$_4$)$_3$ (1055 cm$^{-1}$) and the surface tungsten oxide species (970 cm$^{-1}$) is determined to be 4.5 per unit WO$_3$ content. This ratio agrees well with the intensity ratio of 5 estimated earlier with bulk Al$_2$(WO$_4$)$_3$. The relative intensity of the major Raman band at 1055 cm$^{-1}$ for 10% WO$_3$/Al$_2$O$_3$ sample calcined at 1050°C in Fig. 5b and bulk Al$_2$(WO$_4$)$_3$ from Fig. 1 is 0.10, and is in excellent agreement with the expected value. These measurements confirm the relative Raman cross section of Al$_2$(WO$_4$)$_3$ and its apparent independence on Al$_2$(WO$_4$)$_3$ crystallite size over the range investigated.

FIG. 5. Comparison of Raman spectra for 10% WO$_3$/Al$_2$O$_3$ calcined at (a) 500°C and (b) 1050°C.
The above measurements demonstrate that the relative Raman cross sections of WO₃, Al₂(WO₄)₃, and the surface tungsten oxide species on the alumina are very different in magnitude and do not change over a wide range of particle size and alumina content. This allows for a first-order quantitative prediction of the different tungsten oxide phases present in WO₃/Al₂O₃. This information can now be used to examine previous models of the WO₃/Al₂O₃ system.

Salvati et al. investigated the WO₃/Al₂O₃ (200 m²/g) oxide system with laser Raman spectroscopy as a function of tungsten oxide loading (6). Below 15% WO₃/Al₂O₃ only the surface tungsten oxide species with bands at 973 and 333 cm⁻¹ was present on the alumina surface. Above 15% WO₃/Al₂O₃ three additional bands appeared in the Raman spectra at 807, 715, and 272 cm⁻¹. These bands were shown to be characteristic of crystalline WO₃. X-Ray photoelectron spectroscopy studies demonstrated, however, that the tungsten oxide species present in the catalyst below 30% could not be reduced under conditions where WO₃ reduction normally occurs. Thus, this species was assigned as an octahedral WO₃-like interaction species. The present study shows that because of the very strong Raman cross section of crystalline WO₃, X-Ray photoelectron spectroscopy studies demonstrated, however, that the tungsten oxide species present in the catalyst below 30% could not be reduced under conditions where WO₃ reduction normally occurs. Thus, this species was assigned as an octahedral WO₃-like interaction species.

Salvati et al. estimated the Raman cross section of crystalline WO₃ to the surface tungsten oxide species in WO₃ on SiO₂ using aluminum nitrate as an internal standard (11). They determined by this internal standard method that the Raman cross section of crystalline WO₃ is five to six times higher than that of the surface tungsten oxide species on SiO₂. Previous studies have shown that the structure of the surface tungsten oxide on SiO₂ consists of small 1.2-nm clusters or polymeric units, and that the structure of the surface tungsten oxide on Al₂O₃ is more highly dispersed (7). In view of the above it is not unexpected that differences would be observed in the Raman cross sections of the surface tungsten oxides on these two quite different supports. More work is required to understand the origin of the different relative Raman cross sections of surface metal oxide species.

In conclusion, the model of WO₃ on
Al₂O₃ which emerges is that tungsten oxide is present on the Al₂O₃ surface primarily as a surface oxide species strongly bound to the Al₂O₃ surface. At tungsten oxide loading levels which approach a monolayer, ~0.3 nm²/surface tungsten oxide species, small clusters of WO₃ may be formed which are readily identified by Raman spectroscopy. The detectable limit of WO₃ clusters for WO₃ on Al₂O₃ is less than 0.1 wt% content. Aluminum tungstate formation for γ-Al₂O₃-supported tungsten oxide catalysts is only observed at extremely high calcination temperatures (at 1000°C and above) (2, 5). The detectable limit of Al₂(WO₄)₃ on γ-Al₂O₃ support is less than 1 wt% content.
